Abstract

We study the problem of computing the optimal value function for a Markov decision process with positive costs. Computing this function quickly and accurately is a basic step in many schemes for deciding how to act in stochastic environments. There are efficient algorithms which compute value functions for special types of MDPs: for deterministic MDPs with S states and A actions, Dijkstra's algorithm runs in time $O(AS \log S)$. And, in single-action MDPs (Markov chains), standard linear-algebraic algorithms find the value function in time $O(S^3)$, or faster by taking advantage of sparsity or good conditioning. Algorithms for solving general MDPs can take much longer: we are not aware of any speed guarantees better than those for comparably-sized linear programs. We present a family of algorithms which reduce to Dijkstra's algorithm when applied to deterministic MDPs, and to standard techniques for solving linear equations when applied to Markov chains. More importantly, we demonstrate experimentally that these algorithms perform well when applied to MDPs which "almost" have the required special structure.

Introduction

We consider the problem of finding an optimal policy in a Markov decision process with non-negative costs and a zero-cost, absorbing goal state. This problem is sometimes called the stochastic shortest path problem. Let V^* be the optimal state value function, and let Q^* be the optimal state-action value function. That is, let $V^*(x)$ be the expected cost to reach the goal when starting at state x and following the best possible policy, and let $Q^*(x, a)$ be the same except that the first action must be a . At all non-goal states x and all actions a , V^* and Q^* satisfy *Bellman's equations*:

$$\begin{aligned} V^*(x) &= \min_{a \in A} Q^*(x, a) \\ Q^*(x, a) &= c(x, a) + \sum_{y \in \text{succ}(x, a)} P(y | x, a) V^*(y) \end{aligned}$$

where A is the set of legal actions, $c(x, a)$ is the expected cost of executing action a from state x , and $P(y | x, a)$ is

the probability of reaching state y when executing action a from state x . The set $\text{succ}(x, a)$ contains all possible possible successors of state x under action a , except that the goal state is always excluded.¹

Many algorithms for planning in Markov decision processes work by maintaining estimates V and Q of V^* and Q^* , and repeatedly updating the estimates to reduce the difference between the two sides of the Bellman equations (called the *Bellman error*). For example, value iteration repeatedly loops through all states x performing *backup* operations at each one:

for all actions a

$$\begin{aligned} Q(x, a) &\leftarrow c(x, a) + \sum_{y \in \text{succ}(x, a)} P(y | x, a) V(y) \\ V(x) &\leftarrow \min_{a \in A} Q(x, a) \end{aligned}$$

On the other hand, Dijkstra's algorithm uses *expansion* operations at each state x instead:

$$V(x) \leftarrow \min_{a \in A} Q(x, a)$$

for all $(y, b) \in \text{pred}(x)$

$$Q(y, b) \leftarrow c(y, b) + \sum_{x' \in \text{succ}(y, b)} P(x' | y, b) V(x')$$

Here $\text{pred}(x)$ is the set of all state-action pairs (y, b) such that taking action b from state y has a positive chance of reaching state x . For good recent references on value iteration and Dijkstra's algorithm, see (Bertsekas 1995) and (Cormen, Leiserson, & Rivest 1990).

Any sequence of backups or expansions is guaranteed to make V and Q converge to the optimal V^* and Q^* so long as we visit each state infinitely often. Of course, some sequences will converge much more quickly than others. A wide variety of algorithms have attempted to find good state-visitation orders to ensure fast convergence. For example, Dijkstra's algorithm is guaranteed to find an optimal ordering for a deterministic positive-cost MDP; for stochastic MDPs, algorithms like prioritized sweeping (Moore & Atkeson 1993), generalized prioritized sweeping (Andre, Friedman, & Parr 1998), RTDP (Barto, Bradtke, & Singh 1995), LRTDP (Bonet & Geffner 2003a), and HDP (Bonet & Geffner 2003b) all attempt to compute good orderings.

¹To simplify notation, we have omitted the possibility of discounting. A discount γ can be simulated by reducing $P(y | x, a)$ by a factor of γ for all $y \neq \text{goal}$ and increasing $P(\text{goal} | x, a)$ accordingly. We assume that V^* and Q^* are well-defined, *i.e.*, that no state has infinite $V^*(x)$.

Figure 1: A Markov chain for which backup-based methods converge slowly. Each action costs 1.

Algorithms based on backups or expansions have an important disadvantage, though: they can be slow at policy evaluation in MDPs with even a few stochastic transitions. For example, in the Markov chain of Figure 1 (which has only one stochastic transition), the best possible ordering for value iteration will only reduce Bellman error by 1% with each five backups. To find the optimal value function quickly for this chain (or for an MDP which contains it), we turn instead to methods which solve systems of linear equations.

The policy iteration algorithm alternates between steps of *policy evaluation* and *policy improvement*. If we fix an arbitrary policy and temporarily ignore all off-policy actions, the Bellman equations become linear. We can solve this set of linear equations to evaluate our policy, and set V to be the resulting value function. Given V , we can compute a *greedy policy* π under V , given by $\pi(x) = \arg \min_a Q(x, a)$. By fixing a greedy policy we get another set of linear equations, which we can also solve to compute an even better policy. Policy iteration is guaranteed to converge so long as the initial policy has a finite value function. Within the policy evaluation step of policy iteration methods, we can choose any of several ways to solve our set of linear equations (Press *et al.* 1992). For example, we can use Gaussian elimination, sparse Gaussian elimination, or biconjugate gradients with any of a variety of preconditioners.

Of the algorithms discussed above, no single one is fast at solving all types of Markov decision process. Backup-based and expansion-based methods work well when the MDP has short or nearly deterministic paths without much chance of cycles, but can converge slowly in the presence of noise and cycles. On the other hand, policy iteration evaluates each policy as quickly as possible, but may spend work evaluating a policy even after it has become obvious that another policy is better.

This paper describes three new algorithms which blend features of Dijkstra’s algorithm, value iteration, and policy iteration. To begin with, we describe Improved Prioritized Sweeping. IPS reduces to Dijkstra’s algorithm when given a deterministic MDP, but also works well on MDPs with stochastic outcomes. In the following section, we develop Prioritized Policy Iteration, by extending IPS by incorporating policy evaluation steps. Finally, we describe Gauss-Dijkstra Elimination (GDE), which interleaves policy evaluation and prioritized scheduling more tightly. GDE reduces to Dijkstra’s algorithm for deterministic MDPs, and to Gaussian elimination for policy evaluation. We experimentally demonstrate that these algorithms extend the advantages of Dijkstra’s algorithm to “mostly” deterministic

```

  update( $x$ )

```

Figure 2: Dijkstra’s algorithm, in a notation which will allow us to generalize it to stochastic MDPs. The variable “queue” is a priority queue which returns the smallest of its elements each time it is popped. The constant M is an arbitrary very large positive number.

MDPs, and that the policy evaluation performed by PPI and GDE speeds convergence on problems where backups alone would be slow.

Improved Prioritized Sweeping

Dijkstra’s Algorithm

Dijkstra’s algorithm is shown in Figure 2. Its basic idea is to keep states on a priority queue, sorted by how urgent it is to expand them. The priority queue is assumed to support operations $\text{queue.pop}()$, which removes and returns the queue element with numerically lowest priority; $\text{queue.decreasepriority}(x, p)$, which puts x on the queue if it wasn’t there, or if it was there with priority $> p$ sets its priority to p , or if it was there with priority $< p$ does nothing; and $\text{queue.clear}()$, which empties the queue.

In deterministic Markov decision processes with positive costs, it is always possible to find a new state x to expand whose value we can set to $V^*(x)$ immediately. So, in these MDPs, Dijkstra’s algorithm touches each state only once while computing V^* , and is therefore by far the fastest way to find a complete policy. In MDPs with stochastic outcomes

for some actions, it is in general impossible to efficiently compute an optimal order for expanding states. An optimal order is one for which we can always determine $V^*(x)$ using only $V^*(y)$ for states y which come before x in the ordering. Even if there exists such an ordering (*i.e.*, if there is an acyclic optimal policy), we might need to look at non-local properties of states to find it. See (McMahan & Gordon 2005) for an example of such an MDP.

Several algorithms, most notably prioritized sweeping (Moore & Atkeson 1993) and generalized prioritized sweeping (Andre, Friedman, & Parr 1998), have attempted to extend the priority queue idea to MDPs with stochastic outcomes. These algorithms give up the property of visiting each state only once in exchange for solving a larger class of MDPs. However, neither of these algorithms reduce to Dijkstra’s algorithm if the input MDP happens to be deterministic. Therefore, they potentially take far longer to solve a deterministic or nearly-deterministic MDP than they need to. In the next section, we discuss what properties an expansion-scheduling algorithm needs to have to reduce to Dijkstra’s algorithm on deterministic MDPs.

Generalizing Dijkstra

We will consider algorithms which replace the line (*) in Figure 2 by other priority calculations that maintain that property that when the input MDP is deterministic with positive edge costs an optimal ordering is produced. If the input MDP is stochastic, a single pass of a generalized Dijkstra algorithm generally will not compute V^* , so we will have to run multiple passes. Each subsequent pass can start from the value function computed by the previous pass (instead of from $V(x) = M$ like the first pass), so multiple passes will cause V to converge to V^* . (Likewise, we can save Q values from pass to pass.) We now consider several priority calculations that satisfy the desired property.

Large Change in Value The simplest statistic which allows us to identify completely-determined states, and the one most similar in spirit to prioritized sweeping, is how much the state’s value will change when we expand it. In line (*) of Figure 2, suppose that we set

$$\text{pri} \leftarrow d(V(y) - Q(y, b)) \quad (1)$$

for some monotone decreasing function $d(\cdot)$. Any state y with $\text{closed}(y) = \text{false}$ (called an open state) will have $V(y) = M$ in the first pass, while closed states will have lower values of $V(y)$. So, any deterministic action leading to a closed state will have lower $Q(y, b)$ than any action which might lead to an open state. And, any open state y which has a deterministic action b leading to a closed state will be on our queue with priority at most $d(V(y) - Q(y, b)) = d(M - Q(y, b))$. So, if our MDP contains only deterministic actions, the state at the head of the queue will be the open state with the smallest $Q(y, b)$ —identical to Dijkstra’s algorithm.

Note that prioritized sweeping and generalized prioritized sweeping perform backups rather than expansions, and use a different estimates of how much a state’s value will change when updated. Namely, they keep track of how much a

state’s successors’ values have changed and base their priorities on these changes weighted by the corresponding transition probabilities. This approach, while in the spirit of Dijkstra’s algorithm, do not reduce to Dijkstra’s algorithm when applied to deterministic MDPs. Wiering (1999) discusses the priority function (1), but he does not prescribe the uniform pessimistic initialization of the value function which is given in Figure 2. This pessimistic initialization is necessary to make (1) reduce to Dijkstra’s algorithm. Other authors (for example Dietterich and Flann (1995)) have discussed pessimistic initialization for prioritized sweeping, but only in the context of the original non-Dijkstra priority scheme for that algorithm.

One problem with the priority scheme of equation (1) is that it only reduces to Dijkstra’s algorithm if we uniformly initialize $V(x) \leftarrow M$ for all x . If instead we pass in some nonuniform $V(x) \geq V^*(x)$ (such as one which we computed in a previous pass of our algorithm, or one we got by evaluating a policy provided by a domain expert), we may not expand states in the correct order in a deterministic MDP.² This property is somewhat unfortunate: by providing stronger initial bounds, we may cause our algorithm to run longer. So, in the next few subsections we will investigate additional priority schemes which can help alleviate this problem.

Low Upper Bound on Value Another statistic which allows us to identify completely-determined states x in Dijkstra’s algorithm is an upper bound on $V^*(x)$. If, in line (*) of Figure 2, we set

$$\text{pri} \leftarrow m(Q(y, b)) \quad (2)$$

for some monotone increasing function $m(\cdot)$, then any open state y which has a deterministic action b leading to a closed state will be on our queue with priority at most $m(Q(y, b))$. (Note that $Q(y, b)$ is an upper bound on $V^*(y)$ because we have initialized $V(x) \leftarrow M$ for all x .) As before, in a deterministic MDP, the head of the queue will be the open state with smallest $Q(y, b)$. But, unlike before, this fact holds no matter how we initialize V (so long as $V(x) > V^*(x)$): in a deterministic positive-cost MDP, it is always safe to expand the open state with the lowest upper bound on its value.

High Probability of Reaching Goal Dijkstra’s algorithm can also be viewed as building a set of closed states, whose V^* values are completely known, by starting from the goal state and expanding outward. According to this intuition, we

²We need to be careful passing in arbitrary $V(x)$ vectors for initialization: if there are any optimal but underconsistent states (states whose $V(x)$ is already equal to $V^*(x)$, but whose $V(x)$ is less than the right-hand side of the Bellman equation), then the check $Q(y, b) < V(y)$ will prevent us from pushing them on the queue even though their predecessors may be inconsistent. So, such an initialization for V may cause our algorithm to terminate prematurely before $V = V^*$ everywhere. Fortunately, if we initialize using a V computed from a previous pass of our algorithm, or set V to the value of some policy, then there will be no optimal but underconsistent states, so this problem will not arise.

should consider maintaining an estimate of how well-known the values of our states are, and adding the best-known states to our closed set first.

For this purpose, we can add extra variables $p_{\text{goal}}(x, a)$ for all states x and actions a , initialized to 0 if x is a non-goal state and 1 if x is a goal state. Let us also add variables $p_{\text{goal}}(x)$ for all states x , again initialized to 0 if x is a non-goal state and 1 if x is a goal state.

To maintain the p_{goal} variables, each time we update $Q(y, b)$ we can set

$$p_{\text{goal}}(y, b) \leftarrow \sum_{x' \in \text{succ}(y, b)} P(x' | y, b) p_{\text{goal}}(x')$$

And, when we assign $V(x) \leftarrow Q(x, a)$ we can set

$$p_{\text{goal}}(x) \leftarrow p_{\text{goal}}(x, a)$$

(in this case, we will call a the *selected action* from x). With these definitions, $p_{\text{goal}}(x)$ will always remain equal to the probability of reaching the goal from x by following selected actions and at each step moving from a state expanded later to one expanded earlier (we call such a path a *decreasing path*). In other words, $p_{\text{goal}}(x)$ tells us what fraction of our current estimate $V(x)$ is based on fully-examined paths which reach the goal.

In a deterministic MDP, p_{goal} will always be either 0 or 1: it will be 0 for open states, and 1 for closed states. Since Dijkstra’s algorithm never expands a closed state, we can combine any decreasing function of $p_{\text{goal}}(x)$ with any of the above priority functions without losing our equivalence to Dijkstra. For example, we could use

$$\text{pri} \leftarrow m(Q(y, b), 1 - p_{\text{goal}}(y)) \quad (3)$$

where m is a two-argument monotone function.³

In the first sweep after we initialize $V(x) \leftarrow M$, priority scheme (3) is essentially equivalent to schemes (1) and (2): the value $Q(x, a)$ can be split up as

$$p_{\text{goal}}(x, a)Q_D(x, a) + (1 - p_{\text{goal}}(x, a))M$$

where $Q_D(x, a)$ is the expected cost to reach the goal assuming that we follow a decreasing path. That means that a fraction $1 - p_{\text{goal}}(x, a)$ of the value $Q(x, a)$ will be determined by the large constant M , so state-action pairs with higher $p_{\text{goal}}(x, a)$ values will almost always have lower $Q(x, a)$ values. However, if we have initialized $V(x)$ in some other way, then equation (1) no longer reduces to Dijkstra’s algorithm, while equations (2) and (3) are different but both reduce to Dijkstra’s algorithm on deterministic MDPs.

All of the Above Instead of restricting ourselves to just one of the priority functions mentioned above, we can combine all of them: since the best states to expand in a deterministic MDP will win on any one of the above criteria, we can use any monotone function of all of the criteria and still behave like Dijkstra in deterministic MDPs.

³A monotone function with multiple arguments is one which always increases when we increase one of the arguments while holding the others fixed.

We have experimented with several different combinations of priority functions; the experimental results we report use the priority functions

$$\text{pri}_1(x, a) = \frac{Q(x, a) - V(x)}{Q(x, a)} \quad (4)$$

and

$$\text{pri}_2(x, a) = \langle 1 - p_{\text{goal}}(x), \text{pri}_1(x, a) \rangle \quad (5)$$

The pri_1 function combines the value change criterion (1) with the upper bound criterion (2). It is always negative or zero, since $0 < Q(x, a) \leq V(x)$. It decreases when the value change increases (since $1/Q(x, a)$ is positive), and it increases as the upper bound increases (since $1/x$ is a monotone decreasing function when $x > 0$, and since $Q(x, a) - V(x) \leq 0$).

The pri_2 function uses p_{goal} as a primary sort key and breaks ties according to pri_1 . That is, pri_2 returns a vector in \mathbb{R}^2 which should be compared according to lexical ordering (e.g., $(3, 3) < (4, 2) < (4, 3)$).

Sweeps vs. Multiple Updates

The algorithms we have described so far in this section must update every state once before updating any state twice. We can also consider a version of the algorithm which does not enforce this restriction; this multiple-update algorithm simply skips the check “if not closed(y)” which ensures that we don’t push a previously-closed state onto the priority queue. The multiple-update algorithm still reduces to Dijkstra’s algorithm when applied to a deterministic MDP: any state which is already closed will fail the check $Q(y, b) < V(y)$ for all subsequent attempts to place it on the priority queue.

Experimentally, the multiple-update algorithm is faster than the algorithm which must sweep through every state once before revisiting any state. Intuitively, the sweeping algorithm can waste a lot of work at states far from the goal before it determines the optimal values of states near the goal.

In the multiple-update algorithm we are always effectively in our “first sweep,” so keeping track of p_{goal} doesn’t help us compute accurate priorities. So, with multiple updates, we will use the priority pri_1 from equation (4). The resulting algorithm is called Improved Prioritized Sweeping; its update method is listed in Figure 3.

We also mention here that it is also possible to perform expansions in an incremental manner. If B is a bound on the number of outcomes of each action, this approach performing $O(1)$ work per expansion rather than $O(B)$ as in Figure 3. Doing the full $O(B)$ expansion incorporates newer information about other outcomes as well, and so we did not notice an improvement in performance for the incremental version. For details, please see (McMahan & Gordon 2005).

Prioritized Policy Iteration

The Improved Prioritized Sweeping algorithm works well on MDPs which are moderately close to being deterministic. Once we start to see large groups of states with strongly interdependent values, there will be no expansion order which will allow us to find a good approximation to V^* in a small number of visits to each state. The MDP of Figure 1 is an

```

update( $x$ )
 $V(x) \leftarrow Q(x, \pi(x))$ 
for all  $(y, b) \in \text{pred}(x)$ 
   $Q(y, b) \leftarrow c(y, b) + \sum_{x' \in \text{succ}(y, b)} P(x' | y, b)Q(x', \pi(x'))$ 
  if  $(Q(y, b) < Q(y, \pi(y)))$ 
     $\text{pri} \leftarrow (Q(y, b) - V(y))/Q(y, b)$ 
     $\pi(y) \leftarrow b$ 
     $\text{queue.decreasepriority}(y, \text{pri})$ 

```

Figure 3: The **update** function for the Improved Prioritized Sweeping algorithm. The **main** function is the same as for Dijkstra’s algorithm. As before, “queue” is a priority min-queue and M is a very large positive number.

example of this problem: because there is a cycle which has high probability and visits a significant fraction of the states, the values of the states along the cycle depend strongly on each other. To deal with this, we turn to algorithms that occasionally do some work to evaluate the current policy; the simplest such algorithm is policy iteration.

Prioritized Policy Iteration attempts to improve on policy iteration’s greedy policy improvement step, doing a small amount of extra work during this step to try to reduce the number of policy evaluation steps. Since policy evaluation is usually much more expensive than policy improvement, any reduction in the number of evaluation steps will usually result in a better total planning time.

Pseudo-code for PPI is given in Figure 4. The main loop is identical to regular policy iteration, except for a call to `sweep()` rather than to a greedy policy improvement routine. The policy evaluation step can be implemented efficiently by a call to a low-level matrix solver; such a low-level solver can take advantage of sparsity in the transition dynamics by constructing an explicit LU factorization (Duff, Erisman, & Reid 1986), or it can take advantage of good conditioning by using an iterative method such as stabilized biconjugate gradients (Barrett *et al.* 1994). In either case, we can expect to be able to evaluate policies efficiently even in large Markov decision processes.

The policy improvement step is where we hope to beat policy iteration. By performing a prioritized sweep through state space, so that we examine states near the goal before states farther away, we can base many of our policy decisions on multiple steps of look-ahead. Scheduling the expansions in our sweep according to one of the priority functions previously discussed insures PPI reduces to Dijkstra’s algorithm: when we run it on a deterministic MDP, the first sweep will compute an optimal policy and value function, and will never encounter a Bellman error in a closed state. So Δ will be 0 at the end of the sweep, and we will pass the convergence test before evaluating a single policy. On the other hand, if there are no action choices then PPI will not be much more expensive than solving a single set of linear equations: the only additional expense will be the cost

```

Figure 4: The Prioritized Policy Iteration algorithm. As before, “queue” is a priority min-queue and M is a very large positive number.

of the sweep, which at $O((BA)^2 S \log S)$ is usually much less expensive than solving the linear equations (assuming $B, A \ll S$). For PPI, we chose to use the pri_2 schedule from equation (5). Unlike pri_1 (equation (4)), pri_2 forces us to expand states with high p_{goal} first, even when we have

initialized V to the value of a near-optimal policy.

In order to guarantee convergence, we need to set $\pi(x)$ to a greedy action with respect to V before each policy evaluation. Thus in the **update**(x) method of PPI, for each state y for which there exists some action that reaches x , we recalculate $Q(y, b)$ values for all actions b . In IPS, we only calculated $Q(y, b)$ for actions b that reach x . The extra work is necessary in PPI because the stored Q values may be unrelated to the current V (which was updated by policy evaluation), and so otherwise $\pi(x)$ might not be set to a greedy action. Other Q -value update schemes are possible,⁴ and will lead to convergence as long as they fix a greedy policy. Note also that extra work is done if the loops in **update** are structured as in Figure 4; with a slight reduction in clarity, they can be arranged so that each predecessor state y is backed up only once.

One important additional tweak to PPI is to perform multiple sweeps between policy evaluation steps. Since policy evaluation tends to be more expensive, this allows a better tradeoff to be made between evaluation and improvement via expansions.

Gauss-Dijkstra Elimination

The Gauss-Dijkstra Elimination algorithm continues the theme of taking advantage of both Dijkstra’s algorithm and efficient policy evaluation, but it interleaves them at a deeper level.

Gaussian Elimination and MDPs Fixing a policy π for an MDP produces a Markov chain and a vector of costs c . If our MDP has S states (not including the goal state), let P^π be the $S \times S$ matrix with entries $P_{xy}^\pi = P(y | x, \pi(x))$ for all $x, y \neq \text{goal}$. Finding the values of the MDP under the given policy reduces to solving the linear equations

$$(I - P^\pi)V = c$$

To solve these equations, we can run Gaussian elimination and backsubstitution on the matrix $(I - P^\pi)$. Gaussian elimination calls **rowEliminate**(x) (defined in Figure 5, where Θ is initialized to P^π and w to c) for all x from 1 to S in order,⁵ zeroing out the subdiagonal elements of $(I - P^\pi)$. Backsubstitution calls **backsubstitute**(x) for all x from S down to 1 to compute $(I - P^\pi)^{-1}c$. In Figure 5, $\Theta_{x\cdot}$ denotes the x ’th row of Θ , and $\Theta_{y\cdot}$ denotes the y ’th row. We show updates to $p_{\text{goal}}(x)$ explicitly, but it is easy to implement these updates as an extra dense column in Θ .

Gaussian elimination performed on a Markov chain in this way has a very appealing interpretation: the x th row in Θ

⁴For example, we experimented with only updating $Q(y, b)$ when $P(x | y, b) > 0$ in **update** and then doing a single full backup of each state after popping it from the queue, ensuring a greedy policy. This approach was on average slower than the one presented above.

⁵Using the Θ representation causes a few minor changes to the Gaussian elimination code, but it has the advantage that (Θ, w) can always be interpreted as a Markov chain which is has the same value function as the original (P^π, c) . Also, for simplicity we will not consider pivoting; if π is a proper policy then $(I - \Theta)$ will always have a nonzero entry on the diagonal.

rowEliminate(x)

for y from 1 to $x-1$ do

$$\begin{aligned} w(x) &\leftarrow w(x) + \Theta_{xy}w(y) \\ \Theta_{x\cdot} &\leftarrow \Theta_{x\cdot} + \Theta_{xy}\Theta_{y\cdot} \end{aligned} \tag{1}$$

$$\begin{aligned} p_{\text{goal}}(x) &\leftarrow p_{\text{goal}}(x) + \Theta_{xy}p_{\text{goal}}(y) \\ \Theta_{xy} &\leftarrow 0 \end{aligned}$$

$$w(x) \leftarrow w(x)/(1 - \Theta_{xx})$$

$$\Theta_{x\cdot} \leftarrow \Theta_{x\cdot}/(1 - \Theta_{xx}) \tag{2}$$

$$\Theta_{xx} \leftarrow 0$$

$$p_{\text{goal}}(x) \leftarrow p_{\text{goal}}(x)/(1 - \Theta_{xx})$$

backsubstitute(x)

for each y such that $\Theta_{yx} > 0$ do

$$p_{\text{goal}}(x) \leftarrow p_{\text{goal}}(x) + \Theta_{yx}$$

$$w(y) \leftarrow w(y) + \Theta_{yx}V(x)$$

$$\Theta_{yx} \leftarrow 0$$

if $(p_{\text{goal}}(y) = 1)$

backsubstitute(y)

$$F \leftarrow F \cup \{y\}$$

GaussDijkstraSweep()

while (not queue.empty())

$$x \leftarrow \text{queue.pop}()$$

$$\pi(x) \leftarrow \arg \min_a Q(x, a)$$

$$(\forall y) \Theta_{xy} \leftarrow P(y | x, \pi(x))$$

$$w(x) \leftarrow c(x, \pi(x))$$

rowEliminate(x)

$$v(x) \leftarrow (\Theta_{x\cdot}) \cdot V + w(x)$$

$$F = \{x\}$$

 if $(\Theta_{x, \text{goal}} = 1)$

backsubstitute(x)

$(\forall y \in F)$ **update**(y)

Figure 5: Gauss-Dijkstra Elimination

can be interpreted as the transition probabilities for a macro action from state x , with cost given by $w(x)$. For a full discussion of this relationship, see (McMahan & Gordon 2005).

Gauss-Dijkstra Elimination Gauss-Dijkstra elimination combines the above Gaussian elimination process with a Dijkstra-style priority queue that determines the order in which states are selected for elimination. The main loop is the same as the one for PPI, except that the policy evaluation call is removed and **sweep**() is replaced by **GaussDijkstraSweep**() . Pseudo-code for **GaussDijkstraSweep**() is given in Figure 5.

When x is popped from the queue, its action is fixed to a greedy action. The outcome distribution for this action

is used to initialize Θ_x , and row elimination transforms Θ_x and $w(x)$ into a macro-action as described above. If $\Theta_{x,\text{goal}} = 1$, then we fully know the state’s value; this will always happen for the S th state, but may also happen earlier. We do immediate backsubstitution when this occurs, which eliminates some non-zeros above the diagonal and possibly causes other states’ values to become known. Immediate backsubstitution ensures that $V(x)$ and $p_{\text{goal}}(x)$ are updated with the latest information, improving our priority estimates for states on the queue and possibly saving us work later (for example, in the case when our transition matrix is block lower triangular, we automatically discover that we only need to factor the blocks on the diagonal). Finally, all predecessors of the state popped and any states whose values became known are updated using the `update()` routine for PPI (in Figure 4).

Since S can be large, Θ will usually need to be represented sparsely. Assuming Θ is stored sparsely, GDE reduces to Dijkstra’s algorithm in the deterministic case; it is easy to verify the additional matrix updates require only $O(S)$ work. Initially it takes no more memory to represent Θ than it does to store the dynamics of the MDP, but the elimination steps can introduce many additional non-zeros. The number of such new non-zeros is greatly affected by the order in which the eliminations are performed. There is a vast literature on techniques for finding such orderings; a good introduction can be found in (Duff, Erisman, & Reid 1986). One of the main advantages of GDE seems to be that for practical problems, the prioritization criteria we present produce good elimination orders as well as effective policy improvement.

Our primary interest in GDE stems from the wide range of possibilities for enhancing its performance; even in the naive form outlined it is usually competitive with PPI. We anticipate that doing “early” backsubstitution when states’ values are mostly known (high $p_{\text{goal}}(x)$) will produce even better policies and hence fewer iterations. Further, the interpretation of rows of Θ as macro-actions suggests that caching these actions may yield dramatic speed-ups when evaluating the MDP with a different goal state. The usefulness of macro-actions for this purpose was demonstrated by Dean & Lin (1995). A convergence-checking mechanism such as those used by LRTDP and HDP (Bonet & Geffner 2003a; 2003b) could also be used between iterations to avoid repeating work on portions of the state space where an optimal policy and value function are already known. The key to making GDE widely applicable, however, probably lies in appropriate thresholding of values in Θ , so that transition probabilities near zero are thrown out when their contribution to the Bellman error is negligible. Our current implementation does not do this, so while its performance is good on many problems, it can perform poorly on problems that have significant fill-in.

Experiments

We implemented IPS, PPI, and GDE and compared them to VI, Prioritized Sweeping, and LRTDP. All algorithms were implemented in Java 1.5.0 and tested on a 3Ghz Intel machine with 2GB of main memory under Linux.

	$ S $	f_p	f_ℓ	% determ	O	notes
A	59,780	0.00	0.00	100.0%	1.00	determ
B	96,736	0.05	0.10	17.2%	2.17	$ A = 1$
C	11,932	0.20	0.00	25.1%	4.10	$f_h = 0.05$
D	10,072	0.10	0.25	39.0%	2.15	cycle
E	96,736	0.00	0.20	90.8%	2.41	
F	21,559	0.20	0.00	34.5%	2.00	large-b
G	27,482	0.10	0.00	90.4%	3.00	

Figure 6: Test problems sizes and parameters.

Our PPI implementation uses a stabilized biconjugate gradient solver with an incomplete LU preconditioners as implemented in the Matrix Toolkit for Java (Heimsund 2004). No native or optimized code was used; using architecture-tuned implementations of the underlying linear algebraic routines could give a significant speedup.

For LRTDP we specified a few reasonable start states for each problem. Typically LRTDP converged after labeling only a small fraction of the the state space as solved, up to about 25% on some problems.

Experimental Domain

We describe experiments in a discrete 4-dimensional planning problem that captures many important issues in mobile robot path planning. Our domain generalizes the racetrack domain described previously in (Barto, Bradtke, & Singh 1995; Bonet & Geffner 2003a; 2003b; Hansen & Zilberstein 2001). A state in this problem is described by a 4-tuple, $s = (x, y, dx, dy)$, where (x, y) gives the location in a 2D occupancy map, and (dx, dy) gives the robot’s current velocity in each dimension. On each time step, the agent selects an acceleration $a = (ax, ay) \in \{-1, 0, 1\}^2$ and hopes to transition to state $(x+dx, y+dy, dx+ax, dy+ay)$. However, noise and obstacles can affect the actual result state.

As in the racetrack problem, actions can fail with probability f_p , resulting in a the next state being $(x + dx, y + dy, dx, dy)$. We also model *high-velocity noise*: if the robot’s velocity surpasses an L_2 threshold, it incurs a random acceleration on each time step with probability f_h . States with *local noise* move the robot in a designated direction with probability f_ℓ . We use *one-way passages* to introduce larger cycles into some of our domains.

These additions to the domain allow us to capture a wide variety of planning problems. In particular, kinodynamic path planning for mobile robots generally has more noise (more possible outcomes of a given action as well as higher probability of departure from the nominal command) than the original racetrack domain allows. Action failure and high-velocity noise can be caused by wheels slipping, delays in the control loop, bumpy terrain, and so on. One-way passages can be used to model low curbs or other map features that can be passed in only one direction by a wheeled robot. Local noise can model a robot driving across sloped terrain: downhill accelerations are easier than uphill ones. For more details on the dynamics of our test problem, as well as additional experimental results, please refer to (McMahan & Gordon 2005).

Figure 6 summarizes the parameters of the test problems

Figure 7: Some maps used for test experiments; maps are not drawn to the same scale. Problem (E) uses the same map as (B). Problem (G) uses a smaller version of map (B).

we used. The “% determ” column indicates the percentage of (s, a) pairs with deterministic outcomes.⁶ The O column gives the average number of outcomes for non-deterministic transitions. All problems have 9 actions except for (B), which is a policy evaluation problem. Problem (C) has high velocity noise, with a threshold of $\sqrt{2} + \epsilon$. Figure 7 shows the 2D world maps for most of the problems.

To construct larger problems for some of our experiments, we consider linking copies of an MDP in series by making the goal state of the i th copy transitions to the start state of the $(i + 1)$ st copy. We indicate k serial copies of an MDP M by M^k , so for example 22 copies of problem (G) is denoted (G^{22}) .

Experimental Results

Effects of Local Noise First, we considered the effect of increasing the randomness f_ℓ and f_p for the fixed map (G), a smaller version of (B). One-way passages give this complex map the possibility for cycles. Figure 8 shows the run times (y-axis) of several algorithms plotted against f_p . The parameter f_ℓ was set to $0.5f_p$ for each trial.

These results demonstrate the catastrophic effect increased noise can have on the performance of VI. For low-noise problems, VI converges reasonably quickly, but as noise is increased the expected length of trajectories to the goal grows, and VI’s performance degrades accordingly. IPS performs somewhat better overall, but it suffers from this same problem as the noise increases. However, PPI’s use of policy evaluation steps quickly propagates values through these cycles, and so its performance is almost to-

⁶Our implementation uses a deterministic transition to apply the collision cost, so all problems have some deterministic transitions.

Figure 8: Effect of local noise on solution time. The leftmost data point is for the deterministic problem. Note that PPI-4 exhibits almost constant runtime even as noise is increased.

tally unaffected by the additional noise. PPI-4 beats VI on all trials. It wins by a factor of 2.4 with $f_p = 0.05$ and with $f_p = 0.4$, PPI-4 is 29 times faster than VI.

The dip in runtimes for LRTDP is probably due to changes in the optimal policy, and the number and order in which states are converged. Confidence intervals are given for LRTDP only, as it is a randomized algorithm. The deterministic algorithms were run multiple times, and deviations in runtimes were negligible.

Number of Policy Evaluation Steps Policy iteration is an attractive algorithm for MDPs where policy evaluation via backups or expansions is likely to be slow. It is well known that policy iteration typically converges in few iterations. However, Figure 9 shows that our algorithms can greatly reduce the number of iterations required. In problems where policy evaluation is expensive, this can provide a significant overall savings in computation time.

We compare policy iteration to PPI, where we use either 1, 2, or 4 sweeps of Dijkstra policy improvement between iterations. Policy iteration was initialized to the policy given by the solution of a deterministic relaxation of the problem. We also ran GDE on these problems. Typically it required the same number of iterations as PPI, but we hope to improve upon this performance in future work.

Q-value Computations Our implementation are optimized not for speed but for ease of use, instrumentation, and modification. We expect our algorithms to benefit much more from tuning than value iteration. To show this potential, we compare IPS, PS, and VI on the number of Q -value computations (Q -comps) they perform. A single Q -comp means iterating over all the outcomes for a given (s, a) pair to calculate the current Q value. A backup takes $|A|$ Q -comps, for example. We do not compare PPI-4, GDE, and LRTDP based on this measure, as they also perform other types of computation.

Figure 9: Number of policy evaluation steps.

IPS typically needed substantially fewer Q -comps than VI. On the deterministic problem (A), VI required 255 times as many Q -comps as IPS, due to IPS’s reduction to Dijkstra’s algorithm; VI made 7.3 times as many Q -comps as PS. On problems (B) through (F), VI on average needed 15.29 times as many Q -comps as IPS, and 5.16 times as many as PS. On (G^{22}) it needed 36 times as many Q -comps as IPS. However, these large wins in number of Q -comps are offset by value iteration’s higher throughput: for example, on problems (B) through (F) VI averaged 27,630 Q -comps per millisecond, while PS averaged 4,033 and IPS averaged 3,393. PS and IPS will always have somewhat more overhead per Q -comp than VI. However, replacing the standard binary heap we implemented with a more sophisticated algorithm or approximate queuing strategy could greatly reduce this overhead, possibly leading to significantly improved performance.

Overall Performance of Solvers Figure 10 shows a comparison of the run-times of our solvers on the various test problems. Problem (G^{22}) has 623,964 states, showing that our approaches can scale to large problems.⁷ Biconjugate gradient failed to converge on the initial linear systems produced by PPI-4, so we instead used PPI where 28 initial sweeps were made (so that there was a reasonable policy to be evaluated initially), and then 7 sweeps were made between subsequent evaluations. We also found that adding a pass of standard greedy policy improvement after the sweeps improved performance. These changes roughly balanced the time spent on sweeping and policy improvement. In future work we hope to develop more principled and automatic methods for determining how to split computation time between sweeps and policy evaluation. We did not run PS, LRTDP, or GDE on this problem.

Generally, our algorithms do best on problems that are

⁷This experiment was run on a different (though similar) machine than the other experiments, a 3.4GHz Pentium under Linux with 1GB of memory.

sparsely stochastic (only have randomness at a few states) and also on domains where typical trajectories are long relative to the size of the state space. These long trajectories cause serious difficulties for methods that do not use an efficient form of policy evaluation. For similar reasons, our algorithms do better on long, narrow domains rather than wide open ones; the key factor is again the expected length of the trajectories versus the size of the state space.

Value iteration backed up states in the order in which states were indexed in the internal representation; this order was generated by a breadth-first search from the start state to find all reachable states. While this ordering provides better cache performance than a random ordering, we ran a minimal set of experiments and observed that the natural ordering performs somewhat worse (up to 20% in our limited experiments) than random orderings. Despite this, we observed better than expected performance for value iteration, especially as it compares to LRTDP and Prioritized Sweeping. For example, on the `large-b` problem (F), (Bonet & Geffner 2003b) reports a slight win for LRTDP over VI, but our experiments show VI being faster.

Also, GDE’s performance is typically close to or better than that of PPI-4, except on problem (B), where GDE fails due to moderately high fill in. These results are encouraging because GDE already sometimes performs better than PPI-4, and currently GDE is based on a naive implementation of Gaussian elimination and sparse matrix code. The literature in the numerical analysis community shows that more advanced techniques can yield dramatic speedups (see, for example, (Gupta 2002)), and we hope to take advantage of this in future versions of GDE.

Discussion

The success of Dijkstra’s algorithm has inspired many algorithms for MDP planning to use a priority queue to try to schedule when to visit each state. However, none of these algorithms reduce to Dijkstra’s algorithm if the input happens to be deterministic. And, more importantly, they are not robust to the presence of noise and cycles in the MDP. For MDPs with significant randomness and cycles, no algorithm based on backups or expansions can hope to remain efficient. Instead, we turn to algorithms which explicitly solve systems of linear equations to evaluate policies or pieces of policies.

We have introduced a family of algorithms—Improved Prioritized Sweeping, Prioritized Policy Iteration, and Gauss-Dijkstra Elimination—which retain some of the best features of Dijkstra’s algorithm while integrating varying amounts of policy evaluation. We have evaluated these algorithms in a series of experiments, comparing them to other well-known MDP planning algorithms on a variety of MDPs. Our experiments show that the new algorithms can be robust to noise and cycles, and that they are able to solve many types of problems more efficiently than previous algorithms could.

For problems which are fairly close to deterministic, we recommend Improved Prioritized Sweeping. For problems with fast mixing times or short average path lengths, value iteration is hard to beat and is probably the simplest of all

Figure 10: Comparison of a selection of algorithms on representative problems. Problem (A) is deterministic, and Problem (B) requires only policy evaluation. Results are normalized to show the fraction of the longest solution time taken by each algorithm. On problems (B) and (E), the slowest algorithms were stopped before they had converged. LRTDP is not charged for time spent calculating its heuristic, which is negligible in all problems except (A).

of the algorithms to implement. For general use, we recommend the Prioritized Policy Iteration algorithm. It is simple to implement, and can take advantage of fast, vendor-supplied linear algebra routines to speed policy evaluation.
